

ICER's Reference Case for Economic Evaluations: Elements and Rationale

Current as of October 23, 2025

Domains updated October 2025:

- [Criteria for including the modified societal perspective as a co-base case](#): revised language to indicate that a societal co-base can be presented alongside the health system perspective based on the impact of treatment on societal costs *or* societal health benefits (e.g., caregiver quality of life) instead of societal costs alone.
- [Potential budget impact analyses](#): revised language to indicate that the potential budget impact of a new therapy will be reported using the upper end of ICER's Health Benefit Price Benchmark range (HBPB) (\$150,000 per evLY), and at estimated net pricing, or the placeholder price if a net price estimate is not yet available.
- For a full list of updates, please refer to [Appendix A](#).

Overview

To encourage consistency in analytic approaches when modelling, ICER has defined a “reference case” specifying the approach that ICER and its collaborators follow for cost-effectiveness analyses, analyses of health shortfalls, and potential budget impact analyses. The reference case is defined by the components, methods, and reporting elements to be used in these analyses. ICER’s cost-effectiveness reference case generally aligns with the [Second Panel on Cost-Effectiveness in Health and Medicine](#)’s recommendations for a health care perspective reference case. Note that following the reference case does not preclude additional analyses being conducted, and reasons may exist for deviating from the reference case to reflect particular circumstances. In these cases, any deviations from the reference case will be clearly specified and justified in the model analysis plan and Evidence Report. A summary of ICER’s reference case for cost-effectiveness and potential budget impact analyses is provided in Table 1, with additional details below. This document also includes a description of absolute and proportional shortfall calculations that are used to inform unmet need as a benefit beyond health during committee deliberations. Details can be found in [Section 2: Quantifying Unmet Need \(Proportional and Absolute Quality-Adjusted Life Year \[QALY\] and Equal-Value Life Year \[evLY\] shortfalls\)](#).

Table 1. Overview of ICER’s Reference Case Elements

Element	Specific Details
<i>Decision Problem</i>	
Objectives	<ul style="list-style-type: none">• State the goals of the analysis, specific to the topic area
Target Population	<ul style="list-style-type: none">• Describe the population(s) and setting(s) in which the interventions are to be used<ul style="list-style-type: none">○ Point out any discrepancy between the indicated population and modeled populations and discuss relevance of model results to the indicated population• To the extent possible, conduct subgroup analyses for patient groups that are of clinical or economic interest<ul style="list-style-type: none">○ Specify and define any subpopulation(s) (e.g., defined by demographic or disease characteristics)• Discuss population heterogeneity and subgroups, and likely implications for cost-effectiveness
Intervention	<ul style="list-style-type: none">• Clearly describe the health care intervention(s) being evaluated, including components, dose, duration, etc., as appropriate
Comparators	<ul style="list-style-type: none">• Compare intervention(s) to available and feasible relevant alternative treatments, including specific active comparators, “usual care” (i.e., the treatments currently generally used), or a “do-nothing” option, as appropriate

Element	Specific Details
Perspective	<ul style="list-style-type: none"> • Health care system perspective (default) • Societal perspective as scenario analysis <ul style="list-style-type: none"> ○ Estimate net productivity impacts ○ Include all relevant societal impacts to the extent possible ○ Consider including impact on caregiver quality of life when compelling and appropriate data are available ○ Apply the “non-zero” approach to missing data elements for patient and caregiver productivity time • Present health system perspective in tandem with modified societal perspective as "co-base case" when relevant direct data on societal effects and/or costs are available, and at least one of these conditions is met: <ul style="list-style-type: none"> ○ Impact of treatment on societal effects/costs (e.g., patient and caregiver productivity, education, disability, and nursing home costs) is substantial, and/or ○ The contribution of societal effects/costs to the total effects/costs associated with the condition is judged to be substantial. • The conditions for a co-base case approach will most often be satisfied when the incremental cost-effectiveness ratio changes by greater than 20% or by greater than \$200,000 per evLY gained or QALY, and/or when result crosses thresholds of \$100,000 or \$150,000 per evLY gained or QALY gained • Use Second Panel’s impact inventory (see Appendix B) to document specific health care and societal impacts included, including whether patient out-of-pocket costs are captured
Time Horizon	<ul style="list-style-type: none"> • Lifetime (default) • If shorter, should be long enough to capture all relevant differences in future costs and outcomes associated with treatments being compared, and rationale for shorter duration (e.g., assessment of treatment for acute condition with no long-term sequelae) should be stated
Outcomes	<ul style="list-style-type: none"> • Costs (undiscounted and discounted) • Life-years (undiscounted and discounted) • Quality-adjusted life years (QALYs, undiscounted and discounted) • Equal value life-years gained (evLY gained, undiscounted and discounted) • Other natural outcomes (e.g., hospitalizations avoided), when feasible • Cost per evLY gained • Cost per QALY gained • Cost per life year, if mortality effects • Cost per consequence (e.g., cost per hospitalization avoided), when appropriate and feasible

Element	Specific Details
Model Structure	
Type of Model	<ul style="list-style-type: none"> • Describe the model type (e.g., decision tree, state transition, microsimulation, dynamic transition, dynamic simulation) • Specify the following: <ul style="list-style-type: none"> ○ How events over time are handled (e.g., health states that include event history or number of years in a state, as appropriate) ○ Unit of analysis (e.g., individual, cohort, population) ○ Whether and how individuals can interact with others in the model • State if the model is an existing model or if it was developed <i>de novo</i>
Intervention Effects	<ul style="list-style-type: none"> • Identify all downstream effects of the intervention(s) as they relate to health, resource use, and other economic impacts (health care system and societal) <ul style="list-style-type: none"> ○ Effects of interventions include those that are intended and unintended, both positive (e.g., health improvement) and negative (e.g., serious adverse events) • List all effects of interventions in the Impact Inventory <ul style="list-style-type: none"> ○ Specify the effects of the interventions included in each of the analytic perspectives ○ Justify the rationale for not including any intervention effect in the analysis, if applicable
Event Pathways	<ul style="list-style-type: none"> • Define the pathway of events that stem from how the use of the intervention(s) or comparator(s) relates to each effect included in the analysis <ul style="list-style-type: none"> ○ Events and health states should capture elements of the disease process, not utilization alone • Include conceptual schematic of model
Software	<ul style="list-style-type: none"> • State the software (including version number) used to develop the model

Element	Specific Details
<i>Model Parameters and Data Inputs</i>	
Quantifying Effects of Interventions	<ul style="list-style-type: none"> • For each effect captured in the model, state the method for identifying the treatment effect estimates <ul style="list-style-type: none"> ○ Systematic literature reviews with meta-analyses should be conducted or referenced (e.g., from the Comparative Clinical Effectiveness section of the Evidence Report) ○ When infeasible or impractical to conduct a systematic review, justify data sources used • State and justify assumptions regarding long-term impacts beyond available data, including durability of effect and survival analytic techniques <ul style="list-style-type: none"> ○ For high-impact SSTs, use cure proportion modeling whenever relevant, but also provide survival analysis based on other modeling approaches when feasible • State and justify any corrections for biases or adjustments for transferability in the estimates used in the model
Measurement and Valuation of Health	<ul style="list-style-type: none"> • Health preferences should reflect those of the general US population (preferably); provide rationale if patients with the condition, individuals at heightened disease risk, or a different population is used. • Describe health preferences source/measurement (usually from an indirect method of measurement based on a generic classification system, e.g., EQ-5D-5L), including population, and the methods for seeking and evaluating these inputs, including comprehensive literature review <ul style="list-style-type: none"> ○ Generic preference-based measure is recommended; no specific generic preference-based measure is required, but EQ-5D-5L is preferred if available ○ Use disease-specific preference-based data if generic measures considered non-responsive for relevant health states, or if appropriate generic preference-based data are not available • When there are challenges translating outcome measures used in clinical trials and available patient-reported data into evLYs gained and QALYs, conduct a search for “mapping” studies that allow translation of surrogate outcomes into quality-of-life measures <ul style="list-style-type: none"> ○ Discuss validity of mapping studies and translation into evLYs gained and QALYs, as well as rationale for choosing • If using URD framework, acknowledge and highlight additional uncertainty in translating patient outcomes into evLY gained and QALY measures

<p>Resource Use and Costs</p>	<ul style="list-style-type: none"> • Include all relevant resources and costs based on the health care system perspective. <ul style="list-style-type: none"> ○ Include costs paid by third-party payers ○ Note if costs paid out of pocket by patients are included (or cannot be determined if excluded) ○ Include future related and unrelated health care costs ○ Identify factors included using the impact inventory; identify any excluded costs with rationale • Describe source of cost data and resource utilization, and the methods for how we seek and evaluate those inputs. <ul style="list-style-type: none"> ○ For intervention acquisition costs, the value used in the analysis should consider three factors: 1) whether the treatment is branded, generic, or biosimilar; 2) whether the price is known; and 3) whether the treatment is required to be administered by a provider • Use publicly available data for other health care costs (e.g., Medicare fee schedules, HCUPnet DRG reimbursement rates, or publications using commercial claims data), using consistent sources to the extent possible <p>Converting to Current Year US Dollars</p> <ul style="list-style-type: none"> • Convert all health-related costs to the same year of the model analysis plan in US dollars, using the Personal Consumption Expenditures – Health care services (PCE-H) price index (Table 2.3.4; Line 16) from the Bureau of Economic Analysis (BEA). • When current year costs are not available for non-health care costs, convert costs to current-year US dollars, using the Personal Consumption Expenditures – General (PCE) price index (Table 2.3.4; Line 1) from the Bureau of Economic Analysis (BEA). Inflation of non-health care costs is likely to be a rare occurrence but may occur in the context of conducting an analysis from the societal perspective.
<p>Discounting</p>	<ul style="list-style-type: none"> • 3% per year for both costs and outcomes
<p>Data Assumptions and Limitations</p>	<ul style="list-style-type: none"> • List key data and structural assumptions in a table along with rationale for each, including assumptions related to: <ul style="list-style-type: none"> ○ The natural history of disease ○ Whether there is an associated change in health or additional cost associated with each consequence ○ Extrapolation of short-term data (e.g., from clinical trials) to longer time horizons (e.g., lifetime) <ul style="list-style-type: none"> ▪ For major clinical effects, consider extrapolation scenarios for: <ul style="list-style-type: none"> • No continued effect • Same effect as observed in trial • Diminished effect over time ○ Linking intermediate outcomes (e.g., improvements in disease activity) to long-term outcomes (e.g., reduced mortality)

	<ul style="list-style-type: none"> ○ Extrapolation to other populations (e.g., specific age groups that were not studied in clinical trials) ○ Concordance and treatment discontinuation ○ Calculations of intervention acquisition costs, as appropriate (e.g., if the treatment is dosed according to weight, what weight was used? What discount was applied to new treatments?) ○ Which transitions each intervention is assumed to affect (e.g., does treatment directly affect mortality, or does it only affect short-term or long-term clinical outcomes that have their own association with mortality?) <ul style="list-style-type: none"> • Describe the limitations of the evidence and analysis
Analyses and Results	
Validation	<ul style="list-style-type: none"> • Conduct and describe internal validation checks (e.g., model debugging, checking extreme scenarios) • Check face validity through extensive conversations within ICER’s research team and external experts • Review feedback from external stakeholders to assess model validity • Compare base case results to those from other published analyses
Calibration	<ul style="list-style-type: none"> • Calibration may be used to estimate model parameters for which little or no data exist • Detail calibration procedures used, if applicable, including: <ul style="list-style-type: none"> ○ Data sources for calibration targets ○ Goodness-of-fit metrics ○ Search criteria used to obtain calibration estimates ○ Stopping criteria to determine when calibration is complete
Presentation of Results	<ul style="list-style-type: none"> • For each intervention and comparator, present the following results in tables: <ul style="list-style-type: none"> ○ Costs, including intervention acquisition costs, intervention-related costs, other health care costs, and total costs (undiscounted and discounted) ○ Intervention acquisition costs only to include acquisition costs (not administration or mark-ups) ○ Costs, including intervention acquisition costs, intervention-related costs, other health care costs, and total costs (undiscounted, by year for years 1-5) ○ Life-years (undiscounted and discounted) ○ QALYs (undiscounted and discounted) ○ Equal value life-years gained (evLY gained, undiscounted and discounted) ○ Additional clinical effectiveness measure(s) as appropriate (e.g., hospitalizations avoided) • For each intervention relative to its comparator(s), present the following point estimate results in tables: <ul style="list-style-type: none"> ○ Incremental cost per LY (discounted) ○ Incremental cost per evLY gained (discounted) ○ Incremental cost per QALY (discounted) ○ Incremental cost per other effectiveness measure <ul style="list-style-type: none"> ▪ If the analysis finds a major difference between cost per evLY gained and cost per QALY, include

	<p>specific language describing the underlying characteristics of the treatment and the condition that lead to the difference</p>
<p>Uncertainty and Sensitivity Analyses</p>	<ul style="list-style-type: none"> • Include discussion of “Uncertainty and Controversies” including important alternative model structures and assumptions suggested by stakeholders, and exploration of different conservative or optimistic model variations <ul style="list-style-type: none"> ○ Compare base case results to those from other published analyses • Conduct one-way sensitivity analyses, and present results in tornado diagrams • Conduct threshold analyses for intervention prices to achieve \$50,000, \$100,000, \$150,000, and \$200,000 per evLY gained and per QALY <ul style="list-style-type: none"> ○ Health benefit price benchmark (HBPB) will be reported using standard range from \$100,000 to \$150,000 per evLY gained and QALY ○ Health benefit price benchmark using thresholds linked to the modified societal perspective will also be presented for assessments using a co-base case • Derive expected values of costs and outcomes for each intervention through probabilistic analysis, using sufficient sampling to reflect distributional uncertainty (e.g., 1,000 simulations). <ul style="list-style-type: none"> ○ Report % achieving \$50,000, \$100,000, \$150,000, and \$200,000 per evLY gained thresholds, and graph using scatter plots or cost-effectiveness acceptability curves (CEAC) • Conduct scenario analyses <ul style="list-style-type: none"> ○ Where evidence on distinct subgroups is available, conduct a stratified analysis and present results for each subgroup ○ Conduct analysis using (modified) societal perspective, including productivity, etc.; identify factors included using impact inventory <ul style="list-style-type: none"> ▪ Use Notes column to describe elements deemed to be appropriate for a given model but for which no data are currently available ○ Conduct two scenarios for all high-impact SSTs under review, as well as other, non-SST treatments with relevant and substantial potential cost-offsets (e.g., potential cost offsets >\$1 million over lifetime), generally including threshold analyses for intervention acquisition price: <ul style="list-style-type: none"> ▪ 50/50 shared savings model in which 50% of the lifetime health system cost offsets from a new treatment are assigned to the health system instead of being assigned entirely to the new treatment ▪ Cost-offset cap model in which the health system cost offsets generated by a new treatment are capped at \$150,000 per year but otherwise assigned entirely to the new treatment

	<ul style="list-style-type: none"> ○ When relevant, conduct scenario analysis including limited number of outcome-based payment arrangements <ul style="list-style-type: none"> ▪ In cases where price is known but there is no guidance from stakeholders, exploratory scenario analysis using outcomes and levels of financial risk-sharing that meet specific thresholds may be performed ○ For high-impact SSTs, conduct two scenario analyses to reflect optimistic and conservative assumptions regarding the benefit of SSTs under review, to be presented in conjunction with the base case <ul style="list-style-type: none"> ▪ Inputs for modeling the optimistic and conservative scenarios will be sought beginning with the scoping phase ○ For high-impact SSTs, if intervention acquisition price is known or can be estimated, include a threshold analysis scenario determining duration of beneficial effect for those patients receiving short-term benefit that would be needed to achieve thresholds of \$50,000, \$100,000, \$150,000, and \$200,000 per evLY gained or QALY ○ In cases where an intervention that increases evLYs gained or QALYs is not found to be cost effective with a zero-dollar, or unrealistically low, price, a separate scenario analysis excluding non-intervention health care costs will be presented. The scenario analysis will exclude non-intervention health care costs in a sequential manner starting with the exclusion of unrelated health care costs, followed by related non-intervention health care costs, until a realistic price is achieved. ○ Exploratory scenario analyses to capture impacts of new technologies on disparities in life expectancy across different subpopulations in the US health care system should be conducted when feasible and relevant. Subgroup analyses conducted for racial/ ethnic or socioeconomic status alone should not be conducted ○ Conduct other scenarios as appropriate (e.g., different age cohorts, risk levels, long-term effectiveness, time horizons, utility scales/functions, survival functions, payment strategies)
Potential Budget Impact Analysis	
Eligible Population	<ul style="list-style-type: none"> • Use epidemiologic and other data to estimate size of potential candidate population in the US for each new treatment • Assume an equal proportion of patients (20%) are treated each year over five years, arriving at cumulative 100% at five years.
Time Horizon	<ul style="list-style-type: none"> • Use an undiscounted five-year timeframe
Potential Budget Impact Threshold	<ul style="list-style-type: none"> • Results are compared to a national annual threshold for each new pharmaceutical intervention, updated each calendar year using the most recent inputs available. Current potential budget impact threshold calculations are detailed at https://icer-

	review.org/methodology/icers-methods/icer-value-assessment-framework-2/
<p>Methods</p>	<ul style="list-style-type: none"> • The cost-effectiveness model is used to estimate total costs of each new treatment and comparator, assuming different prices (treatment’s WAC or ASP and net prices or placeholder price, and threshold prices to achieve cost effectiveness at \$50,000, \$100,000, \$150,000, and \$200,000 per evLY gained) • Potential budget impact is defined as total differential cost of using each new therapy rather than relevant existing therapy for the treated population, calculated as differential health care costs (including drug costs) minus any offsets in costs from averted health care events or other aspects of treatment • Evaluate whether a new drug would be likely to take market share from one or more drugs, using clinical expert opinion regarding treatments likely to be displaced by use of a new treatment within the eligible population • Determine whether potential budget impact threshold is reached at each combination of price and percent uptake among eligible patients at five years, following one of the procedures listed below, dependent on whether existing treatments are being displaced <ul style="list-style-type: none"> ○ No existing active treatment: If intervention is for a condition which has no existing active treatment in the market (other than best supportive care), calculate potential budget impact for 100% of the eligible population at the end of five years (20% marginal new uptake per year) ○ Existing treatments launched within prior two years: If intervention is for a condition with existing active treatment(s), one or more of which was launched within the last two years, equal proportions of the eligible population will be split among the intervention and the recently launched treatment(s), with 100% displacement of relevant treatments launched more than two years ago ○ Existing treatments all on market >2 years: If intervention is for a condition with existing active treatment(s) all launched more than two years ago, calculate potential budget impact for 100% of eligible population at end of five years, with displacement of existing treatments ○ Multiple existing treatments: When there are multiple existing treatments on the market, use clinical expert opinion to estimate the percentage of patients converted from each existing treatment to the new treatment ○ Untreated patients: For all cases, include the untreated portion of the eligible population, as long as considered eligible for the new treatment • The analysis will present a cumulative per-patient potential budget impact for each year over the five-year time horizon, with results presented graphically for each intervention assessed, and numerical data presented in tabular format in an appendix

<p>Access and Affordability Alert</p>	<ul style="list-style-type: none"> • Include an access and affordability alert in the final report: <ol style="list-style-type: none"> 1. When the potential budget impact of the intervention at the net price estimate (or placeholder price estimate, if net pricing is not available) crosses the potential budget impact threshold in the potential BIM at the optimal utilization 2. When the potential budget impact of the intervention at the threshold price at \$150,000 per evLY gained crosses the potential budget impact threshold in the potential BIM at the optimal utilization <p>When these scenarios are not met, an access and affordability alert is not issued and the report explains why an alert was not issued (e.g., potential threshold is not crossed at the level of optimal utilization or the price at \$150,000 per evLY gained doesn't cross the potential threshold at the level of optimal utilization)</p>
--	---

BIM: budget impact model, evLY: equal value of life years, evLYG: equal value of life years gained, SST: single and short-term therapies, QALY: quality-adjusted life year, US: United States

Adapted from CADTH Methods and Guidelines, 4th Edition;¹ Neumann et al. CE in Health and Medicine, 2nd Edition.²

1. Explanations

Decision Problem

Objectives

Each reference case analysis should begin with a clear statement of the goals of the analysis (i.e., the research question(s) to be answered). A Model Analysis Plan should be developed for each project using ICER's template, which defines the decision problem to be considered in the economic model. In general, the analysis plan should follow the outline specified in the final scoping document for the project (as published by ICER) or should provide reasons for any deviation from that scope. The Model Analysis Plan will specify the objectives of the economic analysis and the model type (e.g., decision tree, Markov, semi-Markov, microsimulation, discrete event simulation, etc.) to be used for the analysis. In addition, the plan should specify whether the model is an adaptation of an existing model (with references as appropriate) or is being developed *de novo* for this analysis.

Target Population

The reference case should include a detailed description of the populations and settings in which the interventions are to be used. This will generally match the population included in the pivotal trials or indicated in the published or anticipated FDA label, as well as the evaluation's Clinical Effectiveness Review. Justification should be provided when the modeled population differs appreciably from any of these. In addition, any discrepancy between the indicated population and modeled populations, and relevance of model results to the indicated population, will be discussed.

Consistent with our consideration of subgroup analysis in [ICER's white paper on health equity](#), when subpopulations are clearly defined *a priori* by clinical characteristics, it is often an important goal to examine relative cost-effectiveness of treatment in these subpopulations. However, analyses focused on subpopulations based solely by race/ethnicity or socioeconomic status are vulnerable to confounding clinical variables, raising the risk of misinterpretation of results.³ Therefore, in each report we will provide the rationale for why we performed or avoided cost-effectiveness analyses of subpopulations defined by characteristics other than appropriate clinical markers of risk or outcome.

Data permitting, subgroup analyses of appropriate clinical markers of risk or outcome will be considered for patient groups that could be of interest either clinically or economically. Such subgroup analyses have been and will continue to be undertaken when ICER believes that health technologies are likely to be approved or have been used extensively within these subgroups of interest, and as mentioned earlier, pending data availability.

For analyses using cohort or simulation models, the number of patients being modeled, and their key characteristics should be specified. Potential budget impact analyses will use estimates of the eligible US population likely to be treated with the interventions.

Intervention

The health care intervention(s) being evaluated should be clearly described, including components such as mode of administration, dosing, duration of treatment, auxiliary treatments, settings of treatment, etc., as appropriate.

Comparators

The intervention should be compared to the available and feasible relevant treatments that would most likely be used for the target population in the absence of the intervention. This will often represent specific alternative treatments currently available for the target population, some of which may have been active comparators to the intervention in clinical trials; a generally defined “usual care” approach (i.e., a mix of active and supportive care options); or a “do-nothing” option (typically used for placebo comparisons in clinical trials), as appropriate.

Perspective

ICER’s conventional base case will take a health care system perspective as its general standard, including all direct health care-related costs and effects. These are expected to include all relevant costs borne by third-party payers or integrated health systems. Cost sources may also include patient out-of-pocket costs; if so, this should be noted. Decisions to present the patient out-of-pocket component separately should be made based on availability of such data.

In addition, each analysis should include an analysis using a modified societal perspective, which will include costs and outcomes beyond direct health care impacts. Potential domains to include in this modified societal perspective are listed in an impact inventory in [Appendix B](#) (adapted from the Second Panel on Cost-Effectiveness in Health and Medicine.⁴ This inventory should be used to document the specific impacts that are and are not included in both the health care system and modified societal perspectives, as well as the rationale for their inclusion or exclusion.

It is anticipated that, for most analyses, the modified societal perspective will minimally include patient and transportation costs related to treatment, productivity for the patient and caregiver, and disutility for the caregiver. Other indirect costs, such as criminal justice costs, nursing home or assisted living arrangements, and impacts on education, may be included based on relevance to the topic and population of focus.

When direct data are lacking for the impact of an intervention on patient productivity (formal and informal labor, household production, and time seeking care) and caregiver productivity time, an

indirect approach to valuing these domains will be used. To inform estimates for the indirect approach, ICER will use the published relationship between patient utility scores and US-based patient time use data⁵ to derive the anticipated impacts of the treatment on time spent in each activity due to the disease and its management for the patient. Since no parallel relationship between patient utility scores and caregiver time use data exists for the US setting, ICER will assume that caregiver time spent is proportional to 75% of patient formal labor time lost. This estimate is based on the modeled relationship between caregiver time required⁶ and patient time lost⁷ according to patient utility scores in the United Kingdom setting.

In conducting an analysis using the published relationship between patient utility scores and time use, there is an opportunity to continue to capture productivity time lost during periods of non-life extension (which is most consistent with the conventional approach to estimating productivity impacts in cost-effectiveness analysis) while also estimating productivity time gained during periods of life extension. In these circumstances, and in line with the published literature,⁵ the analysis will include patient productivity time lost during non-life extension while estimating patient productivity time gained and patient consumption costs during periods of life extension. Patient consumption costs are not applicable during non-life extension time because they are assumed to apply equally to both the intervention and comparator, and thus, are cancelled out in the incremental analysis. The coefficients for each time use activity are reported in Table 2 of Jiao and Basu 2023,⁵ and a detailed example of the application of the approach is provided in the supplementary materials of the same publication (Table S1.3). For application in an ICER review, hours per day spent on each time use category can be calculated using review-specific age, utility, and disability status (as a percentage of patients who are experiencing a disability) estimates.

In situations where direct data are available for at least one indirect societal cost domain, the modified societal perspective should be undertaken with the available data. A scenario analysis using the indirect “non-zero” approach may be considered in circumstances where the impact of the treatment on indirect societal costs are expected to be substantial and anticipated to be of interest to stakeholders.

We will use the human capital approach⁸ to value all time gained according to the marginal pre-tax wage rate plus fringe benefits⁹ for formal and informal labor time and household production (\$48.05/hour [\$33.02/hour + \$15.03/hour]) and the post-tax (14.5%) wage rate plus fringe benefits for time seeking care ($\$48.05/\text{hour} \times (1 - 0.145) = \41.08 [\$28.23/hour + \$12.85/hour]).¹⁰ Time seeking care is assumed to replace leisure time at the margin. Details are provided in Table 2 below. Patient and caregiver productivity time will be estimated assuming 365.25 days per year, and the same wage rates will be assumed for all patients and informal caregivers regardless of age, sex, and condition. Consumption costs will be calculated in line with the published literature as the annual non-medical consumption per consumer unit divided by the average size of consumer units⁵ (2.5) from the US Bureau of Labor Statistics.¹¹ For 2023, the annual consumption cost is calculated

as \$29,529 - i.e., (total average annual expenditures [\$77,280] – health care related expenditures [\$6,159])/2.5 consumer units) and inflated to the current year (\$29,529) using the [Bureau of Economic Analysis \(BEA\)](#), [Personal Consumption Expenditures – General \(PCE\) price index](#).

Table 2. Valuation of Productivity Time for Patient and Caregiver

Patient and Caregiver Productivity Time	Regression Coefficients (Jiao & Basu 2023) (rc1, rc2, rc3, rc4, rc5, intercept) *	Wage Rate	Fringe Benefits	Tax Rate	References and Notes
Patient Formal Labor Time	Labor coefficients (1.71355, 0.15615, -0.00188, -1.19989, 0.62020, -5.74987)	\$33.02**	\$15.03	NA	BLS data as of June 2025 (Released September 12, 2025) ⁹
Patient Informal Labor Time	Caring for non-household members coefficients (-0.20152, 0.03556, -0.00035, -0.03619, 0.04725, -5.10490) and volunteer activity coefficients (2.48602, 0.00250, 0.00010, -0.38779, 0.09061, -6.73669)				
Patient Household Production	Caring for household members or household services coefficients (0.31294, 0.03769, -0.00037, -0.24830, 0.04762, -3.02665)				
Patient Time Seeking Care	Medical care coefficients (-3.19543, -0.01309, 0.00031, 0.07307, 0.42488, -3.64569)	\$28.23†	\$12.85	14.5%	2022 Federal income tax (accessed September 2025) ¹⁰
Caregiver Productivity Time (Formal Labor)	Proportional to 75% of patient formal labor time lost.	\$33.02**	\$15.03	NA	BLS data as of June 2025 (Released September 12, 2025) ⁹

*Applied using the following algorithm as reported in Jiao and Basu 2023⁵ (hours spent per day): $[\exp(rc1 \times \text{utility} + rc2 \times \text{Age} + rc3 \times \text{Age}^2 + rc4 \times \text{disability status} + rc5 \times \text{disability status} \times \text{utility} + \text{intercept}) / (1 + \exp(rc1 \times \text{utility} + rc2 \times \text{Age} + rc3 \times \text{Age}^2 + rc4 \times \text{Disability status} + rc5 \times \text{disability status} \times \text{utility} + \text{intercept}))] \times 24$. This equation is multiplied by 365.25 productivity days/year to get to an annual number of hours spent within each time domain.

**Pre-tax wage rate

†Post-tax wage rate

What follows is a simplified illustration of the implementation of the indirect “non-zero” approach. Let’s assume that an intervention improves utility in the population by 0.05 over the course of 20 discounted life years. We will assume that the baseline utility of the population is 0.70 and remains

as such for 20 years. There is no difference in survival across the two treatment strategies, the starting age of the population is 60 years, and the disability status is set to 100% of the cohort. If no direct evidence is available on the intervention's impacts on patient productivity time or on caregiver time, then applying the indirect approach would yield \$61,200 in cost offsets related to patient productivity time and \$22,402 in cost offsets related to caregiver productivity time for the intervention versus the comparator across the 20 discounted life years. Consumption costs would be \$0 because there is no difference in survival. If an intervention added one year of discounted survival versus the comparator (assuming the prior conditions remain), there would be \$104,477 in cost offsets related to patient productivity time and \$24,566 cost offsets related to caregiver productivity time. These cost offsets would be reduced by \$28,000 in consumption costs due to the additional year of discounted survival for the intervention versus comparator arm.

Conditions to be met to consider the modified societal perspective as a co-base case

For all interventions, results from the health care system and modified societal perspectives should be presented together as a "co-base case" when relevant direct data on societal effects and/or costs are available, and at least one of these two conditions is met: (1) the impact of treatment on available societal effects/costs is judged to be substantial; (2) the contribution of societal effects/costs to the total effects/costs associated with the condition is judged to be substantial. This will most often occur in cases where the incremental cost-effectiveness ratio changes by greater than 20%, greater than \$200,000 per evLY or QALY gained, or when the result crosses the threshold of \$100,000 or \$150,000 per evLY or QALY gained.

Time Horizon

To attempt to ensure that all downstream costs and effects are accounted for, the default time horizon for ICER's reference case will be lifetime. In some cases, the nature of the condition or intervention being studied, or the lack of long-term data may necessitate the use of a shorter horizon. However, in such cases, the shorter time horizon should still be long enough to capture all relevant differences in future costs and outcomes associated with the treatments being compared. Time horizon may also be considered as a parameter of interest in sensitivity analyses.

Outcomes

The specific model outcomes should be specified. Costs, life-years, equal value life-years gained (evLYG),¹² and quality-adjusted life-years (QALYs), both undiscounted and discounted, should be tabulated. Analysts should also present results for other outcomes as natural units (e.g., cost per treatment response, cost per event averted), when feasible. Cost-utility analysis (CUA) with incremental cost per evLY gained and cost per QALY reported as the primary outcomes will be the default choice for ICER's reference case. Analysts should also present results in terms of cost per

life year gained and incremental costs for clinical outcome achieved (e.g., cost per treatment response, cost per event averted), when appropriate and feasible.

Model Structure

Type of Model

The type of model relates to the specified decision problem. Broadly, types of models include decision trees, state-transition cohort models, microsimulation models, dynamic transmission models, or dynamic simulation models. Models can also include components with different model types; for example, a model may include a decision tree for an initial (shorter) period, followed by a state-transition model for longer-term extrapolations. Decision trees are suitable when there are no recurrent events and when the time horizon is short. State-transition models of cohorts (also called Markov cohort models) capture changing health states over time. Microsimulation models simulate individuals, which can be advantageous when modeling complex disease or care processes; microsimulations should model a sufficient number of individuals to achieve stable results (assessed by calculating variance over multiple runs).¹³ Dynamic transmission models capture the interactions between individuals, which is suited for decision problems where the transmission of disease is important (e.g., infectious diseases). Dynamic simulation models (e.g., discrete event simulations, agent-based models) are best suited for decision problems evaluating systems with competing demands for resources (such as settings of care) or interactions between individuals (such as transmission of disease).

The type of model will relate to the following factors: (a) how time is handled; (b) the unit of analysis; and (c) the interactions of individuals in the model. Time can be fixed (e.g., decision tree), treated as discrete (e.g., state-transition models), or continuous (e.g., discrete event simulations). In addition, events over time may be allowed to vary, which must be handled appropriately (e.g., health states defined by prior event history or duration of time). The unit of analysis can be an individual or cohort; if an individual unit of analysis is considered, the total number of individuals will be specified and justified. If individuals are allowed to interact with others or with a system, the dynamic components of the model should be described.

The Model Analysis Plan and Evidence Report will also specify if the model was used or modified from existing sources or was developed *de novo*. If modified from existing sources, the appropriate references will be provided.

Intervention Effects

All effects of the intervention(s) as they relate to health, resource use, and other economic impacts will be identified through the scoping process. The effects of the intervention include those which are intended and unintended, with positive or negative impacts. The effects included in an analysis

will depend on the perspective (e.g., health care system or modified societal), and will be guided by practical considerations (e.g., data availability). To clarify the effects included in a model and analysis, the Impact Inventory will be completed (see [Appendix B](#)). The Impact Inventory is a formal framework for considering and specifying the effects included in the analyses using the health system payer and modified societal perspectives. If an identified effect is not included in an analysis, the rationale will be provided with justifications.

Wherever feasible, inputs on clinical effectiveness should match those reported in the Clinical Effectiveness Review, including estimates derived by any quantitative synthesis of the data (e.g., network meta-analysis on relative risk of hospitalization).

Event Pathways

The method by which the intervention(s) and comparator(s) relate to the included effects will be detailed. The sequence or pathway of events stemming from first use of the intervention(s) should capture not only health care utilization, but also the key elements of the disease process. A conceptual diagram or model schematic will be provided, which visually represents the event pathway and health states built into the model structure.

Software

The software, including version and any analysis packages, used to develop the model will be specified in the Model Analysis Plan and Evidence Report.

Model Parameters and Data Inputs

Quantifying Effects of Interventions

A systematic literature review is the preferred method for identifying relevant literature pertaining to the estimates of treatment effect, and in some cases, adverse events. For each effect captured in the model, the systematic review will be referenced (e.g., from the clinical review section of the Evidence Report). When it is infeasible or impractical to conduct a systematic review for a particular effect estimate, the data source used will be justified.

Analysts should state and justify assumptions regarding long-term impacts beyond the available data, including those around durability or maintenance of effect and which survival analytic techniques were considered and used. For high-impact SSTs, models should use cure proportion modeling whenever relevant, but also provide survival analyses based on other modeling approaches when relevant and feasible.

If there is evidence to suggest the identified treatment effect estimates from the existing literature are biased or otherwise not transferable to the context of the model, any adjustments or corrections used will be detailed and specified.

Measurement and Valuation of Health

Reference case models should include all relevant health outcomes, including serious adverse events that impact costs or quality of life. In general, measures of health state preferences (utility) should reflect those of the general US population, as ICER models primarily inform decisions at the population level (e.g., payer or health system formulary decisions) that involve individuals both with and without the condition of focus.

Where general population estimates are not available or appropriate, different populations may be used, such as patients with the specific condition under study, those affected by similar symptoms, proxy respondents, or mixed samples, with appropriate rationale provided. In all cases, a description of the sources and methods used for health preferences measurement should be provided. This will often involve a method of measuring health states in patients that are then mapped into a generic classification system with associated utility weights, such as the EQ-5D-5L.

In general, the use of generic, preference-based measures for utility values is recommended. While no specific generic, preference-based measure is required, EQ-5D-5L preference-based values are preferred if available. As the most widely used generic measure, this helps ensure comparability across studies. Models should use disease-specific preference-based data if generic measures are considered not to be responsive enough to distinguish relevant health states or treatment attributes, or if appropriate generic preference-based data are not available.

When there are challenges in translating the outcome measures used in clinical trials or available patient-reported data into evLYs gained or QALYs gained, analysts should conduct a search for “mapping” studies that allow translation of surrogate outcomes into quality-of-life measures. If used, the report should discuss the validity of the mapping studies and their translation into evLYs gained and QALYs gained, as well as the rationale for choosing specific mapping algorithms. If an analysis is using the ultra-rare disease ([URD framework](#)), the model report should acknowledge and highlight additional uncertainty in translating patient outcomes into evLYs and QALYs, if relevant.

Resource Use and Costs

The reference case model should include all relevant resources and costs based on the health system perspective including costs paid by third-party payers, including future related and unrelated health care costs, and noting whether out of pocket expenses for patients are included. Any excluded costs should be identified, with the rationale for exclusion provided. The sources for resource utilization and cost data should be provided, along with the methods for how those inputs

were identified and evaluated, including details of the comprehensive literature review. The acquisition cost (and any applicable mark-up) for the intervention that HBPBs are being calculated should not be included in sensitivity analyses.

Please refer to [Appendix D \(Calculating Intervention Acquisition Costs\)](#) and [Appendix E \(Guidance for the Inclusion of Future Health Care Costs\)](#) for further details.

Intervention acquisition costs

For intervention acquisition costs, the cost included in the economic evaluation is dependent on three factors, including: 1) whether the treatment is a generic, biosimilar, or branded product; 2) whether the treatment is required to be administered by a provider; and 3) whether the price is known yet.

For generic treatments that do not require provider administration and a price is known, the acquisition price is based on the median cost (WAC) across all generic versions in the model unless a specific branded or generic formulation is being analyzed, for which the median price for that specific branded or generic formulation would be used. This price should be varied in sensitivity analyses using the lowest and highest generic price reported. RED BOOK is the primary source for identifying these acquisition costs. No separate net price is estimated given the generic nature of the treatment. The WAC is used as the acquisition cost throughout all analyses and throughout the report.

For biosimilar treatments that do not require provider administration, and a price is known, the acquisition price is based on the median cost (WAC) across all biosimilar versions in the model unless a specific biosimilar formulation is being analyzed, for which the median price for that specific biosimilar formulation would be used. This price should be varied in sensitivity analyses using the lowest and highest biosimilar price reported. RED BOOK is the primary source for identifying these acquisition costs. If data is available, a separate net price should be calculated following the methods used for branded treatments below. This net price should be used in the base case and sensitivity analyses and the WAC price should be used when calculating the percent discount needed to reach each HBPB.

For generic and biosimilar treatments that require provider administration, and a price is known, the acquisition price is based on the price from the average sales price (ASP) drug pricing file that is updated quarterly. The price from this file is inclusive of the ASP and the associated mark-up. When modeling the price, remove the mark-up (typically calculated as the ASP+6%) and program the mark-up in a separate input. Then the model will track a drug price that is reflective of the ASP in one input and a separate input that is reflective of the mark-up. The two inputs when summed, equate to the value found in the ASP Drug Pricing File. For biosimilars, the mark-up is calculated at 6% of the original biologic and thus the price of the original biologic should be used when

estimating the amount of the relative mark-up. The ASP is used as the acquisition cost throughout all analyses and throughout the report. The intervention acquisition cost used throughout the report (e.g., unit cost, annual cost, lifetime intervention acquisition costs in the results, undiscounted intervention acquisition costs used in BIM, price on which percent discounts to reach a health benefit price benchmark [HBPB] are needed) should not be inclusive of the mark-up. A footnote should be added to tables and clarifying text should be added to the report to clearly detail that the total costs include the mark-up but when the intervention acquisition cost is presented it is specific to the acquisition cost alone.

For branded treatments that do not require provider administration, and a price is known, the intervention acquisition WAC price should be equivalent to the median WAC across all applicable formulations. RED BOOK is the primary source for identifying these acquisition costs. A separate intervention acquisition net price should also be estimated. This net price should be used in the base case and sensitivity analyses and the WAC price should be used when calculating the percent discount needed to reach each HBPB. In situations where a new product under review has a recently announced launch price and no information is provided by the manufacturer on discount from WAC, the WAC price should be used.

To calculate the net price:

- (1) Apply the average discount (over four quarters; obtained from SSR Health, LLC or IPD Analytics Rebate Monitor) to the WAC price to calculate the net price, or
- (2) If SSR Health net prices or rebate data from IPD Analytics are not available or not considered reliable, review the Federal Supply Schedule (FSS) and calculate a discount of the FSS price from the WAC price, or
- (3) If neither SSR Health, IPD Analytics, nor FSS have the treatment in their data, ask the manufacturer to provide the average discount or net price; if the discount or net price provided is a range, use the conservative end of the range, or
- (4) If neither SSR Health, IPD Analytics, nor the FSS have the treatment in their data, and the manufacturer does not provide a discount or net price, review SSR Health and IPD Analytics for a net price or an estimated discount, respectively, for treatments in the same class or treatments that are considered analogs, or
- (5) If no estimate from manufacturers and no treatments in the same class or treatments are considered analogs, use the average discount for brand drugs from IQVIA global trends reports.

In the report, use the net price in the conventional base-case and sensitivity analyses. Use the WAC or ASP when calculating the percent discount needed to reach each HBPB. Provide BIM inputs separately for the WAC or ASP and net price, as well as the three thresholds.

For branded treatments that require provider administration, and a price is known, estimate the acquisition price by retrieving the price from the ASP drug pricing file. This price is inclusive of the

ASP and the associated mark-up. When modeling the price, remove the mark-up (typically calculated as the ASP+6%) and program the mark-up in a separate input. Then the model will track a drug price that is reflective of the ASP in one input and a separate input that is reflective of the mark-up. The two inputs when summed, equate to the value found in the ASP Drug Pricing File. The ASP is used as the acquisition cost throughout all analyses and throughout the report and a separate net price is not identified for treatments that require provider administration. The intervention acquisition cost used throughout the report (e.g., unit cost, annual cost, lifetime intervention acquisition costs in the results, undiscounted intervention acquisition costs used in BIM, price on which percent discounts to reach HBPBs are needed) should not be inclusive of the mark-up. A footnote should be added to tables and clarifying text should be added to the report to clearly detail that the total costs include the mark-up but when the intervention acquisition cost is presented it is specific to the acquisition cost.

For branded treatments that do not require provider administration but do not have a price that is publicly available:

- 1) Ask the manufacturer to provide the expected price;
- 2) If they do not, search for investor analysts' opinions or earnings calls transcripts on launch price;
- 3) If still not available and there are other similar drugs in the class, calculate the average net price across these drugs (using net pricing steps described in the section for branded treatments with a price available that do not require provider administration) and use that average as the placeholder price for the treatment;
- 4) If no analysts' price and no similar drugs in the class, calculate prices to reach thresholds of \$50,000/evLY gained, \$100,000/evLY gained, \$150,000/evLY gained, and \$200,000/evLY gained.

If selecting option 4, use the price to achieve \$100,000 per evLY gained in all sensitivity and scenario analyses. Regardless of specific approach, the price selected will be a placeholder price and should be identified as such throughout the review with clarifying text and footnotes to respective result displays. The placeholder price is assumed to be inclusive of any discount and thus no separate net price is identified. The placeholder price is used in the conventional base-case and sensitivity analyses. If using a placeholder, HBPBs will still be calculated, but the percent discount needed to reach each HBPB will not be calculated. Provide BIM inputs for the placeholder price.

For branded treatments that do require provider administration but do not have a price that is publicly available, follow the steps under the section for branded treatments without a price available that do not require provider administration but then add a 6% mark-up. Program the mark-up in a separate input in the inputs tab. Then the model will track a placeholder price in one input and a separate input that is reflective of the mark-up. The placeholder price estimated is assumed to be inclusive of any discount. No separate net price will be identified. The placeholder price is used in the conventional base-case and sensitivity analyses. If using a placeholder, HBPBs

will still be calculated, but the percent discount needed to reach each HBPB will not be calculated. Provide BIM inputs for the placeholder price. The intervention acquisition cost used throughout the report (e.g., unit cost, annual cost, lifetime intervention acquisition costs in the results, undiscounted intervention acquisition costs used in BIM, price on which percent discounts to reach HBPBs are needed) should not be inclusive of the mark-up. A footnote should be added to tables and clarifying text should be added to the report to clearly detail that the total costs include the mark-up but when the intervention acquisition cost is presented it is specific to the acquisition cost.

To the extent possible, analysts should use publicly available data for other health care costs (e.g., Medicare fee schedules, HCUPnet DRG reimbursement rates, or publications using commercial claims data). Models should include cost data from consistent sources to the extent possible.

Converting to Current Year US Dollars

All costs should be converted to current-year US dollars, using foreign exchange rates.¹⁴

Convert all health-related costs to the same year of the model analysis plan in US dollars, using the [Personal Consumption Expenditures – Health care services \(PCE-H\) price index \(Table 2.3.4\)](#) from the [Bureau of Economic Analysis \(BEA\)](#).

To convert costs to current-year dollars, identify a price index for the starting year and then ending (or current) year. For the starting year, click modify in the top, right corner of the webpage for Table 2.3.4 and select “Annual” for your starting year. The starting year reflects what year the cost data are in the source identified. Scroll down to row 16 of the table for health care services to obtain the price index for that year. Similarly, to select the price index for the ending year, scroll down to row 16 of the table for health care services to obtain the price index for the most recent year that data are available. The end year reflects the present value (or as near as possible). Divide the price index from the ending year by the price index for the starting year. That value will be what you multiply by the cost input from the source to inflate the cost input to present value.

Example: At the time the model analysis plan is published, there is a source from 2008 for the cost (\$2,000) of managing post-surgical complications in the US that aligns with the population of interest. To convert this value to current year, for example, January 3, 2022, US dollars, use the most recent annual price index available (which in this case was a 2020 price index). The cost estimates would be inflated to 2020 US Dollars as follows:

$$\begin{aligned} &= \$2,000 \times \left(\frac{\text{Annual Price index for 2020}}{\text{Annual Price index for 2008}} \right) \\ &= \$2,000 \times \left(\frac{112.513}{91.606} \right) \\ &= \$2,456.45 \end{aligned}$$

When current year costs are not available for non-health care costs, convert costs to current-year US dollars, using the [Personal Consumption Expenditures – General \(PCE\) price index \(Table 2.3.4; Line 1\)](#) from the [BEA](#). The same methods that were used for health care costs apply. Inflation of non-health care costs is likely to be a rare occurrence but may occur in the context of conducting an analysis from the modified societal perspective. Please see [Appendix C](#) for an illustrative summary of guidance for converting to current year US dollars.

Discounting

To account for time value and ensure comparability across studies, all models should use constant-rate discounting of both costs and outcomes, at the rate of 3% per year, as recommended by the Second Panel on Cost-Effectiveness in Health and Medicine.⁴

Data Assumptions and Limitations

All key assumptions used in the model should be listed in a table, along with the rationale for each assumption and sources of relevant data. This should include assumptions related to the natural history of disease, whether there is an associated change in health or additional cost associated with each consequence, and the method for extrapolation of short-term data (e.g., from clinical trials) to longer time horizons (e.g., lifetime). For extrapolation of major clinical effects, analysts should consider extrapolation scenarios for no continued effect, the same effect as observed in trial data, and diminished effect over time. Additional assumptions to list include: the process for linking intermediate outcomes (e.g., improvements in disease activity) to long-term outcomes (e.g., reduced mortality), extrapolation to other populations (e.g., specific age groups that were not studied in clinical trials), and the handling of adherence and treatment discontinuation. Any assumptions or inputs used in the calculation of intervention acquisition costs should be described, as appropriate, such as the weight assumed if the treatment is dosed according to weight. In addition, the model transitions that each intervention is assumed to affect should be described, such as whether treatment directly affects mortality or only affects other short-term or long-term clinical outcomes.

Finally, any limitations of the evidence available or of the methods or analytic techniques should be described in the report of the cost-effectiveness analysis.

Analyses and Results

Validation

Validation of an economic model occurs throughout the development process. Internal model validation (e.g., model debugging, checking extreme scenarios) is conducted. Face validity (e.g., the model structure and processes are appropriate for the decision problem) is checked through extensive conversations within ICER's research team and external experts. In addition, ICER reviews

feedback from external stakeholders in their assessment of validity. Reference case methods and results are also compared to those from other published analyses of the relevant interventions or therapy area, with rationale for any differences observed. These validation procedures and results should be described in any reporting of model methods and results.

Calibration

In some models, there may be parameters for which little or no data exist. For these parameters, calibration may be used as an estimation technique. Calibration is an iterative process that entails finding values for parameters such that the projected model outputs match (i.e., “fit”) the observed data (i.e., calibration targets). If calibration is performed, the procedures will be detailed including: (a) the data sources for the calibration targets; (b) the goodness-of-fit metric(s) used, such as a likelihood-based metric or distance measure; (c) how the parameter space was searched, for example using a grid-based search or an algorithm; and (d) the stopping criteria to determine when the calibration is complete.

Presentation of Results

The model should be used to conduct a deterministic base case analysis (if appropriate for model type), following these reference case guidelines to the extent possible. Outcomes from the model should be presented for each intervention and comparator and will generally include all of the following. Reported output from the model should include undiscounted and discounted costs, life-years, evLYs gained, and QALYs gained. In addition to these outcomes, if appropriate, at least one clinical effectiveness measure should be tallied, such as hospitalizations avoided by treatment or absolute rates of hospitalization for each intervention and comparator. Discounted costs, broken out into costs for the intervention and comparators, other health care costs, and total costs, should also be reported. In addition, the model output should provide undiscounted costs (including intervention/comparator costs, other health care costs, and total costs) broken out by year for years one through five, for use in potential budget impact analyses. Finally, the discounted incremental cost per life-year, incremental cost per evLY gained, and incremental cost per QALY should be calculated for each intervention-versus-comparator pair. If appropriate, incremental cost per other effectiveness measure should also be calculated for each intervention-versus-comparator pair. In specific cases where appropriate (e.g., mutually exclusive interventions used in the same population), incremental cost per outcome may be presented for comparisons between interventions as well. If the analysis finds a major difference between cost per QALY and cost per evLY gained, specific language will be included to describe the underlying characteristics of the treatment and the condition that lead to the differences.

Uncertainty and Sensitivity Analyses

Economic evaluations will include discussion of “Uncertainty and Controversies,” including important alternative model structures and assumptions suggested by manufacturers and other stakeholders, and exploration of different conservative or optimistic model variations, in particular, any alternative model structures or inputs that differ importantly from the base case. This sub-section consolidates and expands discussion of factors related to uncertainty, including lack of information on natural history, limitations of the data on patient outcomes, difficulties translating existing data into measures of quality of life, and disagreements over the plausibility of certain inputs or assumptions.

Summaries of relevant published cost-effectiveness analyses are also included in this sub-section, pointing out differences in model structure, inputs and assumptions, and the impact of these differences on model results. This section will review and compare the current model to published models that included the same interventions or comparators of interest, were developed in the last 10 years, and were similar to the current model from a setting and population perspective.

To account for uncertainty, one-way sensitivity analyses should be conducted, and results should be presented in “tornado diagrams” that display the findings across a feasible range for each parameter estimate. In addition, the model output should provide threshold analyses to determine the intervention prices that would be estimated to achieve common willingness-to-pay thresholds of \$50,000, \$100,000, \$150,000, and \$200,000 per QALY and per evLY gained. In addition to deterministic sensitivity analyses, the model should derive expected values of costs and outcomes for each intervention through probabilistic sensitivity analysis, using sufficient sampling to reflect distributional uncertainty (e.g., 5,000 simulation runs if feasible). Output from this analysis should include a table reporting the percent of simulations that achieve \$50,000, \$100,000, \$150,000, and \$200,000 per evLY gained thresholds, as well as graph(s) using scatter plots or cost-effectiveness acceptability curves (CEAC).

Specific scenario analyses should be conducted where appropriate. Where evidence on distinct subgroups is available, analysts should conduct a stratified analysis and present results for each subgroup. In line with [ICER’s white paper on health equity](#), analyses focused on subpopulations based solely by race/ethnicity or socioeconomic status alone should not be conducted. As mentioned above, a scenario using a modified societal perspective should be modeled, with the included productivity and other impacts identified using an impact inventory table.

Economic evaluations will include two analyses for all high-impact SSTs under review, as well as other, non-SST treatments with relevant and substantial potential cost-offsets, such as potential cost offsets that are greater than \$1 million over a lifetime. These scenarios may include threshold-based price analyses based on the following:

- A 50/50 shared savings model in which 50% of the lifetime health system cost offsets from a new treatment are assigned to the health system instead of being assigned entirely to the new treatment, and
- A cost-offset cap model in which the health system cost offsets generated by a new treatment are capped at \$150,000 per year but otherwise assigned entirely to the new treatment.

When relevant, evaluations will include information from manufacturers and payers to model a scenario analysis including a limited number of outcome-based payment arrangements for the intervention under review. In cases where the WAC (and discount from WAC) or ASP of the treatment is known but there is no guidance from stakeholders, an exploratory scenario analysis using outcomes and levels of financial risk-sharing that could meet cost-effectiveness thresholds may be performed.

In addition to the base case and associated sensitivity analyses, economic evaluations will include two specific scenario analyses to reflect an optimistic and a conservative assumption regarding the benefit of SSTs under review. Input for best approaches to modeling the optimistic and conservative scenarios will be sought beginning with the scoping phase and will be included as part of the model analysis plan. These scenario analyses will be presented in conjunction with the base case.

For high-impact SSTs, when the SST price is known or can be estimated, assessments will also include a scenario with a threshold analysis determining the duration of beneficial effect (e.g., cure) for those patients receiving short-term benefit that would be needed to achieve standard cost-effectiveness thresholds of \$50,000, \$100,000, \$150,000, and \$200,000 per evLY gained and QALY.

In cases where an intervention that increases evLYs and/or QALYs is not found to be cost effective with a zero-dollar, or an unrealistically low, price a separate scenario analysis excluding non-intervention health care costs will be presented. By non-intervention health care costs, ICER means all costs except those directly tied to administering the intervention or other modeled treatment options (i.e., comparator costs). In such cases, there are no positive prices for an intervention that will reach specific cost-effectiveness thresholds. This may occur in situations where a new treatment is added to existing treatment that is already near or beyond the cost-effectiveness threshold. Another example where this may occur is when a new treatment results in more time spent in health states that have very high related or unrelated non-intervention health care costs and/or a low utility value, making it impossible for the incremental cost effectiveness ratio to reach

specific thresholds even at zero price. In such cases a scenario analysis excluding health state costs that are not related to the intervention *per se* may be informative. The scenario analysis will exclude non-intervention health care costs in a sequential manner starting with the exclusion of unrelated health care costs, followed by related non-intervention health care costs, until a realistic price is achieved. In situations where the modified societal perspective is considered a co-base case and the intervention is not found to be cost effective with a zero-dollar, or an unrealistically low, price, the same scenario analysis will be performed.

Other scenario analyses can be considered on a topic-specific basis as appropriate, including different age cohorts, risk levels, long-term effectiveness assumptions, time horizons, utility scales or functions, survival functions, or payment and contracting strategies.

The health benefit price benchmark (HBPB) will continue to be reported using the standard range from \$100,000 to \$150,000 per QALY and per eVLY gained. In situations where realistic HBPBs are only calculable using the scenario described above (i.e., excluding non-intervention health care costs), this scenario may be used to generate the benchmark at the discretion of the ICER review team. The health benefit price benchmark using thresholds linked to the modified societal perspective will also be presented for assessments using a co-base case.

Potential Budget Impact Analyses

Eligible Population

Potential budget impact analyses are based on annual, non-cumulative net or placeholder (usually equal to net of another agent or average or weighted average of a therapeutic class) interventional cost per patient, non-interventional cost per patient, and estimates of the proportion of the US population eligible for treatment with the new intervention. ICER uses epidemiologic and other data (e.g., market share data) to estimate the size of the potential candidate population for each new treatment. For generally prevalent models, the model will assume that an equal proportion of prevalent patients (20%) would be treated with the new treatment each year over five years, arriving at a cumulative 100% uptake at five years; for generally incident models, the model will assume that one incident cohort would be treated in each of the five years, for a total of five incident cohorts treated over the potential budget impact analysis time horizon. When analyzing the budget impact of multiple new interventions, the eligible patient population is split equally across all new interventions. See the [Methods](#) section below for additional information on allocation of eligible patients.

Time Horizon

The potential health care system budgetary impact of the intervention is explored over a five-year time horizon. Results from the cost-effectiveness model are used to provide undiscounted (with

regard to time horizon) net or placeholder costs (including intervention/comparator costs, other health care costs, and total costs) broken out by year for years one through five, for use in the potential budget impact analyses.

Perspective

Potential budget impact analysis takes the health system perspective and thus includes all direct medical health care expenditures covered and reimbursed by third-party payers or others furnishing care (e.g., integrated health care delivery networks). Patient out-of-pocket costs should not be removed as part of the base-case analysis, and similarly, should not be removed from the cost-effectiveness annual cost outputs that feed into the budget impact model. Should stakeholders take interest in removing patient cost share from estimates of the payer's budget impact, they can do so via the [ICER Analytics Interactive Modeler](#) platform. If a modified societal co-base case is included in the cost-effectiveness analysis, these costs should not be included in ICER Reports as they represent costs exterior to the health care sector or health system perspective.

Methods

ICER uses the cost-effectiveness model in an economic evaluation to estimate the potential total budgetary impact of new treatments in the US, assuming different prices, including the treatment's placeholder or actual net price (or ASP for physician administered drugs), and if relevant and available, WAC price, and the three threshold prices to achieve cost effectiveness at \$50,000, \$100,000, \$150,000, and \$200,000 per evLY gained. Potential budget impact is defined as the total differential cost of using each new therapy rather than relevant existing therapy for the treated population, calculated as differential health care costs (including drug costs) minus any offsets in these costs from averted health care events.

ICER will continue to use clinical expert opinion regarding the treatments likely to be displaced by use of a new treatment within the eligible population. ICER will then follow one of the procedures listed below, dependent on whether existing treatments are being displaced. These are explicitly NOT meant to represent our assumptions of the budget impact of new interventions that are most likely in the real world. Our methods are intended to provide the calculations that can underpin a graphic figure that allows decision-makers and policy makers to make their own assumptions.

- No existing active treatment: If the intervention is for a condition which has no existing active treatment in the market (other than standard care), we will calculate potential budget impact for 100% of the eligible population at the end of five years (20% incremental new uptake per year).
- Existing treatments launched within prior two years: If the intervention is for a condition with existing active treatment(s), one or more of which was launched within the last two

years, equal proportions of the eligible population will be split among the intervention and the recently launched treatment(s), with 100% displacement of all relevant treatments launched more than two years ago.

- Existing treatments all on market >2 years: If the intervention is for a condition with existing active treatment(s) all launched more than two years ago, we will calculate potential budget impact for 100% of the eligible population at the end of five years, with displacement of all existing treatments. Initial market shares for existing treatments must be applied.
 - Multiple existing treatments: When there are multiple existing treatments on the market, clinical expert opinion will be used to estimate the percentage of patients converted from each existing treatment to the new treatment.
- Mix of existing treatments launched within two years and >2 years:
 - See “existing treatments launched within prior two years” bullet above
- Untreated patients: For all cases, we will include the untreated portion of the eligible population, as long as they are considered eligible for the new treatment.

The analysis will present a cumulative per-patient potential budget impact for each year over the five-year time horizon, with results presented graphically for each intervention assessed, and average annual per-patient potential budget impact data presented in tabular format in an appendix of the report.

Potential Budget Impact Threshold

The goal of ICER’s potential budget impact analysis is to estimate the net budget impact per patient treated with new interventions so that decision-makers can use their own assumptions about uptake and pricing to determine their own estimate of potential budget impact. We also seek to produce calculations that will help policymakers identify situations in which the potential uptake of a new treatment, at various pricing levels, might exceed a budget impact threshold that signifies that the budget impact in the near term (over five years) would contribute to overall health care cost growth at a higher rate than growth in the national economy (plus 1%). Results of the analysis are compared to a potential budget impact national annual threshold for each new pharmaceutical intervention, updated each calendar year using the most recent inputs available. Current potential budget impact threshold calculations are detailed [here](#).

Access and Affordability Alert

Within the potential budget impact analysis section of each final report, we will include a subsection discussing whether ICER is issuing an “Access and Affordability alert”. The goal of the alert is to signal that the additional health care costs introduced by a new intervention may be difficult for the health care system to absorb over the short term. In this situation, other needed

services may be displaced, or health care insurance costs may rapidly rise, which would threaten sustainable access to high-value care for all patients.

In addition to highlighting the potential budget impact of the intervention when using the upper end of ICER's Health Benefit Price Benchmark range (HBPB) (\$150,000 per evLY), we will also report the budget impact of the therapy at either estimated net pricing, or the placeholder price if a net price estimate is not yet available. Our goal in reporting both estimates (the placeholder or net price, as well as the threshold price) is to determine whether there would be significantly different impacts on affordability at these various prices. For example, we will call attention to situations where the alert would be triggered by the placeholder price or net price, but not by the threshold price. In other situations, the alert may be triggered (or not) regardless of which price is used, and this will be described as well.

2. Quantifying Unmet Need (QALY and evLY Shortfalls)

As stated in ICER’s Value Assessment Framework, giving priority to treatments according to “lifetime burden of illness” or “need” best represents the ethical instincts of a society or other decision-makers. To inform unmet need as a benefit beyond health, ICER provides empirical results for the absolute shortfall and proportional shortfall. Shortfalls are commonly measured using the QALY but can also be measured using the evLY (or evLY gained). As described in ICER’s Value Assessment Framework, concerns regarding the valuation of life extension by the QALY lead ICER to emphasize the evLY gained as the metric in the health benefit price benchmark and other elements of determining the overall value of treatments. For shortfall considerations, ICER will emphasize the results of shortfalls based on the evLY gained but will retain information on QALY results for benchmarking with academic and international efforts.

The absolute shortfall is defined as the total absolute amount of future health patients with a condition are expected to lose without the treatment that is being assessed.¹⁷ The ethical consequences of using absolute shortfall to prioritize treatments is that conditions that cause early death or that have very serious lifelong effects on quality of life receive the greatest prioritization. Thus, certain kinds of treatments, such as treatments for rapidly fatal conditions of children, or for lifelong disabling conditions, score highest on the scale of absolute shortfall.

The proportional shortfall is measured by calculating the proportion of the total health units of remaining life expectancy that would be lost due to untreated illness. The proportional shortfall reflects the ethical instinct to prioritize treatments for patients whose illness would rob them of a large percentage of their expected remaining lifetime. As with absolute shortfall, rapidly fatal conditions of childhood have high proportional shortfalls, but high numbers can also often arise from severe conditions among older adults who may have only a few years left of average life expectancy but would lose much of that to the illness without treatment.

To calculate the absolute QALY shortfall for a condition, subtract the lifetime undiscounted quality-adjusted life expectancy for the current standard of care for that condition from the lifetime undiscounted quality-adjusted life expectancy for the general population (calculated using age- and sex-adjusted estimates for mortality and age-adjusted estimates for quality of life). The quality-adjusted life expectancy for the general population is calculated using the same baseline age and sex distribution as what was modeled for the condition’s standard of care. To calculate the proportional QALY shortfall for each condition, divide the absolute QALY shortfall by the quality-adjusted life expectancy for the general population with the same age and sex distribution at baseline.

The calculations for the absolute evLY shortfall and proportional evLY shortfall are equivalent to the calculations for the QALY shortfalls except the quality-adjusted component of the life expectancy calculation does not vary by age but is rather fixed at 0.851 for all ages. Therefore, to calculate the absolute evLY shortfall for each condition, subtract the lifetime undiscounted equal-value life expectancy for the current standard of care for that condition from the lifetime undiscounted equal-value life expectancy for the general population (calculated using age- and sex-adjusted estimates for mortality and a constant 0.851 for quality of life). The life expectancy for the general population is calculated using the same baseline age and sex distribution as the condition's standard of care. To calculate the proportional evLY shortfall for each condition, divide the absolute evLY shortfall by the equal-value (using a constant 0.851 for all ages) life expectancy for the general population with the same age and sex distribution at baseline.

For each ICER assessment the shortfall estimates will be displayed and compared to a league table of past ICER assessment shortfalls. Table 3 shows the absolute and proportional QALY and evLY shortfalls for conditions assessed in prior ICER reviews.

Table 3. Absolute and Proportional QALY and evLY Shortfalls for Conditions Assessed in Prior ICER Reviews

Condition	Absolute QALY Shortfall	Absolute evLY Shortfall	Proportional QALY Shortfall	Proportional evLY Shortfall
Acute Pain	0.2	0.2	0.8%	0.8%
Alzheimer's Disease	8.8	9.4	70.1%	71.3%
Amyotrophic Lateral Sclerosis	18.6	19.4	95.2%	95.4%
Atopic Dermatitis	8.6	9.9	25.1%	27.7%
Chronic Kidney Disease	17.2	18.1	77.8%	78.7%
Beta Thalassemia	25.0	25.5	52.0%	52.5%
Bladder Cancer	6.1	6.6	55.6%	57.5%
Cardiovascular Disease	2.9	3.5	18.2%	21.4%
Chronic Obstructive Pulmonary Disease	7.5	8.1	51.8%	53.8%
COVID-19 Outpatient	1.0	2.1	3.8%	7.7%
COVID-19 Inpatient	1.8	2.7	9.2%	12.9%
Depression	8.4	9.7	29.1%	32.0%
Diffuse Large B-Cell Lymphoma	16.1	16.9	82.2%	82.9%
Duchenne Muscular Dystrophy	52.7	51.9	85.8%	85.6%
Epstein-Barr Virus Positive Post-Transplant Lymphoproliferative Disease	25.2	26.4	89.0%	89.5%
Hemophilia	10.8	10.9	21.7%	21.9%
Hereditary Angioedema	1.8	3.0	5.3%	8.8%
High Cholesterol	1.1	1.7	7.2%	10.9%
Hypertrophic Cardiomyopathy	0.0	0.0	0%	0%
IgA Nephropathy	17.5	18.7	57.9%	59.0%
Lupus Nephritis	20.7	22.1	54.2%	55.8%
Menopause	0.0	0.0	0%	0%
Multiple Myeloma	17.9	18.7	95.6%	95.7%
Myelodysplastic Syndrome-Induced Anemia	8.2	8.7	74.3%	73.2%
Narcolepsy	9.4	9.4	22.7%	24.5%
Nonalcoholic Steatohepatitis	8.9	9.9	40.1%	42.5%
Non-Cystic Fibrosis Bronchiectasis	6.5	7.3	34.0%	36.6%
Obesity	5.0	6.2	17.0%	20.4%
Osteoporosis	2.0	2.6	15.0%	18.7%
Pediatric B-Cell Acute Lymphoblastic Leukemia	54.2	53.9	93.9%	93.9%
Peanut Allergy	0.0	0.0	0%	0%
Prostate Cancer	3.1	3.6	32.5%	35.6%
Retinal Disease	22.4	21.6	34.1%	33.3%
Retinitis Pigmentosa	14.9	14.9	70.7%	70.7%

Severe Asthma	3.2	4.2	12.8%	16.4%
Smoking Cessation	10.0	11.0	41.3%	43.6%
Spinal Muscular Atrophy	55.8	54.8	82.0%	81.7%
Tardive Dyskinesia	10.3	11.6	29.7%	32.3%
Transthyretin Amyloid Cardiomyopathy	5.1	5.5	62.1%	63.9%
Ulcerative Colitis	5.3	6.6	16.2%	19.3%

evLY: equal-value life year, QALY: quality-adjusted life year

Appendix A. Record of Amendments

Version	Date	Summary of Amendments
V1.0	Jan. 31, 2020	Last updated version of original Reference Case
V2.0	Sept. 23, 2023	<ul style="list-style-type: none"> • Modified societal perspective: When direct data on patient and caregiver productivity are lacking, analyses will be performed using an “indirect approach” based on QALY gains so that parameter inputs will be “non-zero.” • Quantifying unmet need: ICER will provide empirical results for the absolute shortfall and proportional shortfall to inform deliberation and voting on unmet need as a contextual consideration during public meetings. • Enhanced clarity on methods: drug pricing, inflation, subgroup analyses, and affordability and access alert domains.
V2.1	September 30, 2024	<ul style="list-style-type: none"> • Intervention acquisition costs: Recommendation to use the median cost of generics and biosimilar agents instead of the lowest cost, differentiated costing approaches for generic and biosimilar agents, added a flow chart (Appendix C) to offer greater clarity on recommended approach to calculating intervention acquisition costs. • Inclusion of future unrelated health care costs: Explicit recognition that future unrelated health care costs will be included in the base case analysis. • Guidance for situations where an intervention is not found to be cost effective at a zero-dollar, or an unrealistically low, price: Updated recommendation to exclude non-intervention health care costs in a sequential manner starting with the exclusion of unrelated health care costs, followed by related non-intervention health care costs, until a realistic price is achieved.
V2.2	October 23, 2025	<ul style="list-style-type: none"> • Criteria for including the modified societal perspective as a co-base case: revised language to indicate that a societal co-base case can be presented alongside the health system perspective based on the impact of treatment on societal costs <i>or</i> societal health benefits (e.g., caregiver quality of life) instead of societal costs alone. • Potential budget impact analyses: revised language to indicate that the potential budget impact of a new therapy will be reported using the upper end of ICER’s Health Benefit Price Benchmark range (HBPB) (\$150,000 per evLY), and at estimated net pricing, or the placeholder price if a net price estimate is not yet available.

Note: Updates to Table 3. Absolute and Proportional QALY and evLY Shortfalls for Conditions Assessed in Prior ICER Reviews are updated on a continuous basis as the ICER Final Evidence Reports are posted.

Appendix B. Impact Inventory (adapted from Neumann, Sanders et al.⁴)

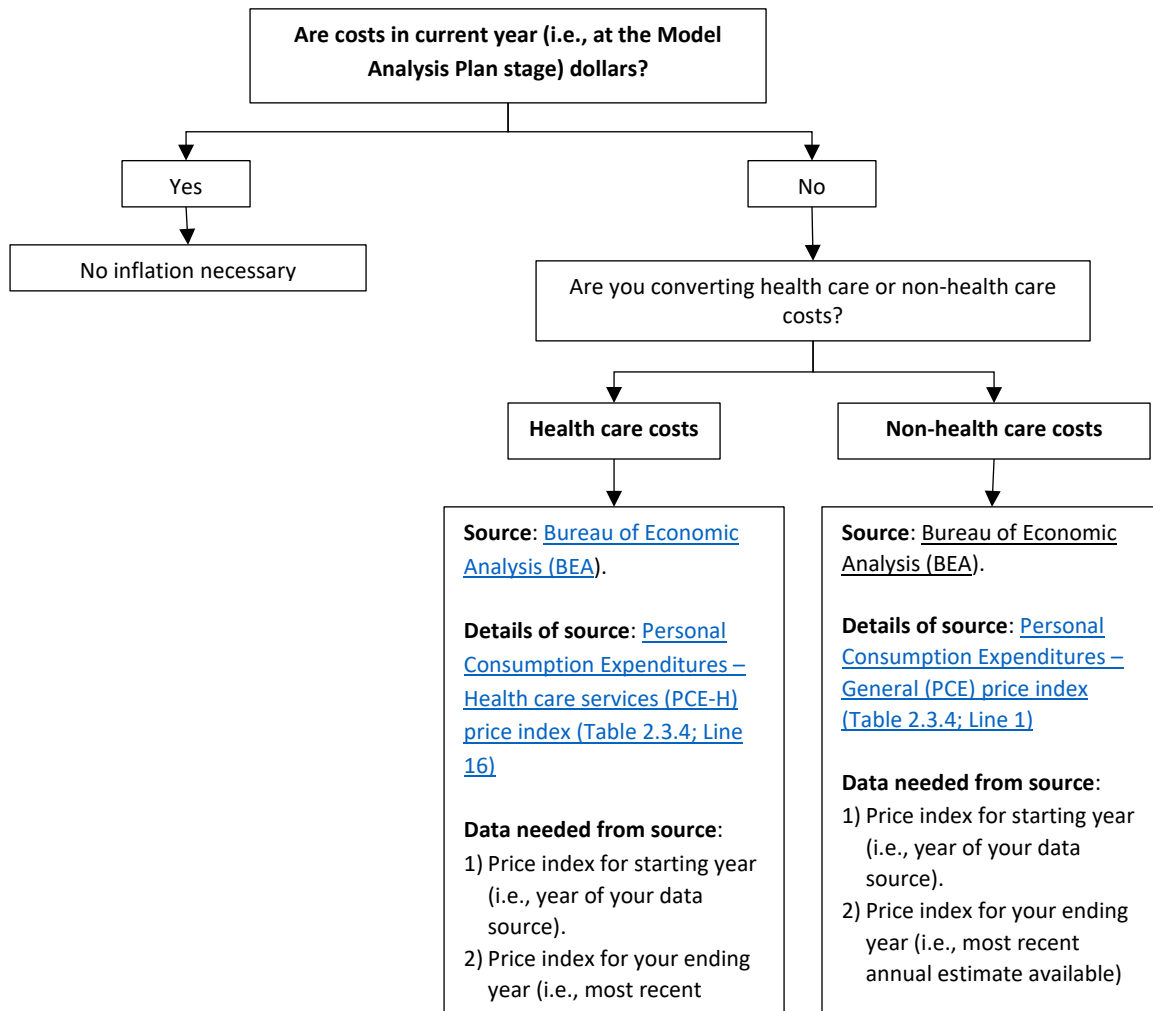

Note that the purpose of this checklist is to report whether different impacts were considered in the health system payer and modified societal perspective analyses. Not all impact types will be relevant for every intervention. For example, some interventions may have impacts limited to the formal health care sector, while other interventions may have substantial impacts beyond the formal health care sector.

Sector	Type of Impact (Add additional domains, as relevant)	Included in This Analysis from... Perspective?		Notes on Sources (if quantified), Likely Magnitude & Impact (if not)
		Health Care Sector	Societal	
Formal Health Care Sector				
Health outcomes	Longevity effects	<input type="checkbox"/>	<input type="checkbox"/>	
	Health-related quality of life effects	<input type="checkbox"/>	<input type="checkbox"/>	
	Adverse events	<input type="checkbox"/>	<input type="checkbox"/>	
Medical costs	Paid by third-party payers	<input type="checkbox"/>	<input type="checkbox"/>	
	Paid by patients out-of-pocket	<input type="checkbox"/>	<input type="checkbox"/>	
	Future related medical costs	<input type="checkbox"/>	<input type="checkbox"/>	
	Future unrelated medical costs	<input type="checkbox"/>	<input type="checkbox"/>	
Informal Health Care Sector				
Health-related costs	Patient time costs	NA	<input type="checkbox"/>	
	Unpaid caregiver-time costs	NA	<input type="checkbox"/>	
	Transportation costs	NA	<input type="checkbox"/>	
Non-Health Care Sectors				
Productivity	Labor market earnings lost	NA	<input type="checkbox"/>	
	Cost of unpaid lost productivity due to illness	NA	<input type="checkbox"/>	
	Cost of uncompensated household production	NA	<input type="checkbox"/>	
Consumption	Future consumption unrelated to health	NA	<input type="checkbox"/>	
Social services	Cost of social services as part of intervention	NA	<input type="checkbox"/>	
Legal/Criminal justice	Number of crimes related to intervention	NA	<input type="checkbox"/>	
	Cost of crimes related to intervention	NA	<input type="checkbox"/>	
Education	Impact of intervention on educational achievement of population	NA	<input type="checkbox"/>	
Housing	Cost of home improvements, remediation	NA	<input type="checkbox"/>	

Environment	Production of toxic waste pollution by intervention	NA	<input type="checkbox"/>	
Other	Other impacts (if relevant)	NA	<input type="checkbox"/>	

NA: not applicable

Appendix C. Converting to Current Year US Dollars

Appendix D. Calculating Intervention Acquisition Costs

Appendix E. Guidance for the Inclusion of Future Health Care Costs

Inclusion of Future Health Care Costs in ICER Reviews

ICER has clarified its recommended approach for the inclusion of future health care costs in its assessments. Future health care costs include future costs related and unrelated to the condition under review, both of which represent real costs to the health system. In alignment with the Recommendations from the Second Panel on Cost-Effectiveness in Health and Medicine, ICER recommends that all future related and unrelated health care costs be included in the base case analysis.

Future related health care costs include the costs of survival and the costs of death which *are related to the condition under review* and are included in all analyses.

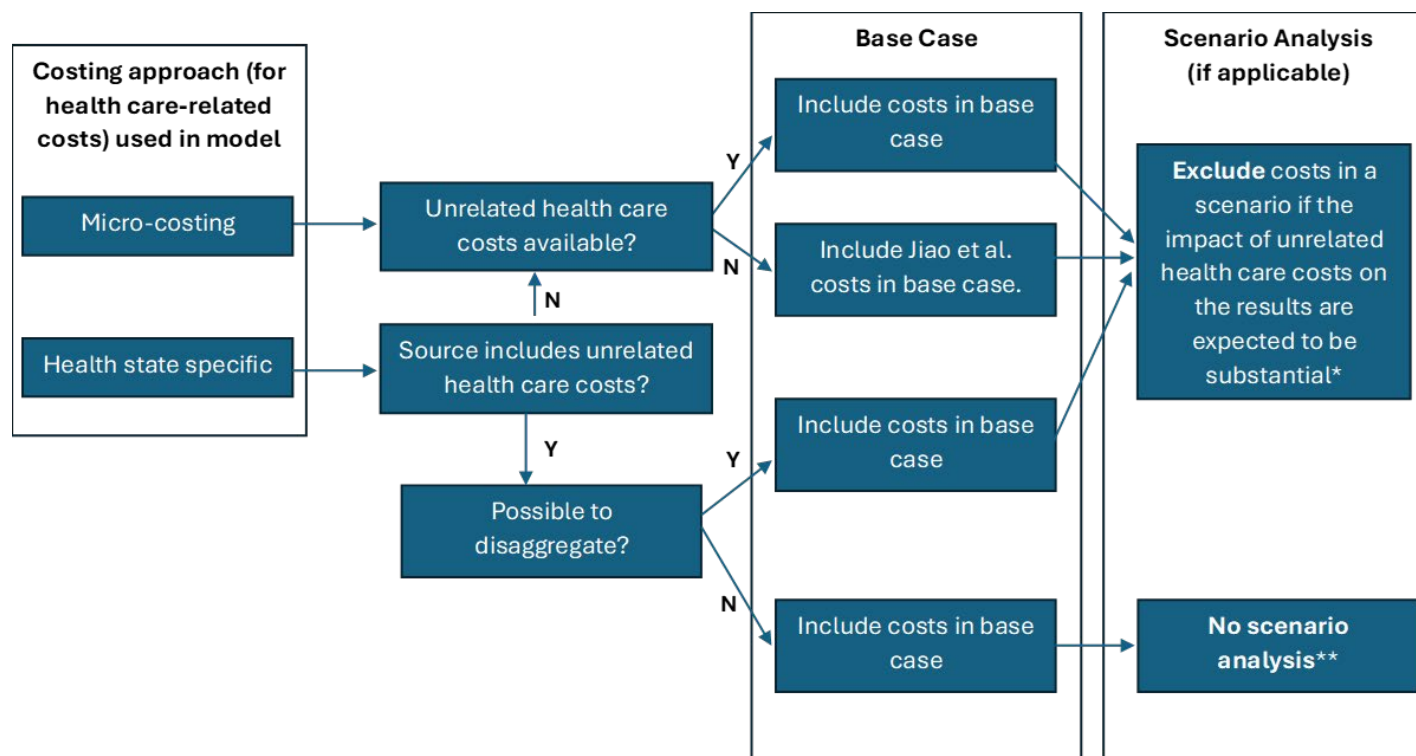

Future unrelated health care costs include both the costs of survival and the costs of death which *are not related to the condition under review*. ICER's recommended approach is outlined in **Figure E1** and summarized below:

- If a **micro-costing approach** is used to capture future health care costs included in the economic model, modelers should seek to identify unrelated health care costs among the population of interest for the review from available sources (e.g., data request, literature review, patient groups, etc.). If available, these costs should be included in the base case. If not available, general age and sex-specific costs from [Jiao & Basu 2021](#) (non-condition specific, costs of survival and death), inflated to the current year, should be included in the base case.
- If a **health-state specific costing approach** is used to capture future health care costs in the economic model, modelers should identify if unrelated health care costs are included:
 - If **unrelated health care costs are included**, these costs should remain included in the base case and a note should be made in the costing section of the report to indicate that both related and unrelated costs are included in the estimate. This can also be specified in the Impact Inventory (Appendix B).
 - If **unrelated health care costs are not included**, modelers should seek to identify unrelated health care costs among the population of interest for the review from available sources (e.g., data request, literature review, patient groups, etc.). If available, these costs should be included in the base case. If not available, general age and sex-specific costs from [Jiao & Basu 2021](#) (non-condition specific, costs of survival and death) inflated to the current year should be included in the base case.

Importantly, ICER recognizes that there may be situations where the inclusion of unrelated health care costs may have a substantial impact on the results. Substantial is defined as when incremental cost-

effectiveness ratio changes by greater than 20% or by greater than \$200,000 per evLY or QALY gained, and/or when result crosses thresholds of \$100,000-\$150,000 per evLY or QALY gained. For example, this may occur when assessing high severity conditions and/or conditions that result in substantial life extension. In these cases, a scenario analysis that removes the future unrelated health care costs from the analysis may be warranted and should be discussed within the ICER review team for a given topic; the final decision on whether to include such a scenario rest with the review team. If a **health-state specific costing approach** is used to capture future health care costs in the economic model and it is **not possible to disaggregate these costs from related health care costs** when a scenario analysis is deemed relevant, the report should specify that unrelated health care costs are included, and that no scenario analysis was performed because disaggregated costs were not available.

Figure E1: Considerations for including unrelated future health care costs in ICER model base case and scenario analysis

* Substantial is defined as when incremental cost-effectiveness ratio changes by greater than 20% or by greater than \$200,000 per evLY or QALY gained, and/or when result crosses thresholds of \$100,000-\$150,000 per evLY or QALY gained.

**Report to specify that unrelated health care costs are included, and that no scenario analysis was performed because disaggregated costs were not available.
